

# an interpreted imperative programming language that wants to believe

#### Lorenzo Loconte

#### Introduction

**Shrimp** is a simple imperative programming language designed during the course of *Formal Methods for Computer Science* at Universita' degli Studi di Bari Aldo Moro. **Shrimp** uses an *eager evaluation strategy*. In order to ensure that, the interpreter executes the code using the *call by value* method.

### Software Modules

The program is composed by three main components:

- The parser
- The optimizer
- The interpreter

The **parser** takes in input the source code and convert it to an intermediate representation. The intermediate representation (IR) have the structure of a n-ary tree having the non-terminals of the grammar as internal nodes and commands, identifiers and constants on the leaves.

The **optimizer** takes in input the intermediate representation given by the parser. The result of the optimizer is an *optimized* intermediate representation. It evaluates the constant expressions (both arithmetic and boolean) that might be present in the source code and replace them with the resulting constants. The optimizer also checks for empty commands block and useless branch statements.

The **interpreter** execute the semantics present in an intermediate representation. The basic idea is to use a **state** (or environment) that collects the values of the variables during the execution of the program. The result of the interpretation is the resulting state, that is a set of assignments to the variables.

# The Language Syntax

The syntax for the **Shrimp** programming language is a context-free grammar. So, it can be denoted using EBNF (Extended Backus Naur Form) as following:

```
Type ::= "int"
  Integer ::= [0-9]+
3 | Identifier := [a-zA-Z_]+
4 | Program ::= "shrimp" Block
5 Block ::= [Command]*
  Command ::= {Assignment | Branch | Loop}
  Assignment ::= Identifier "=" ArithmeticExpr ";"
  Branch ::= "if" "(" BooleanExpr ")" "then" Block
              ["else" Block] "end if" ";"
9
  Loop ::= "while" "(" BooleanExpr ")" "do"
10
            Block "end while" ";"
11
12
13
  ArithmeticExpr ::=
       ArithmeticTerm "+" ArithmeticExpr
14
     | ArithmeticTerm "-" ArithmeticExpr
15
     | ArithmetciTerm
16
17
  ArithmeticTerm ::=
       ArithmeticFactor "*" ArithmeticTerm
18
     | ArithmeticFactor "/" ArithmeticTerm
19
     ArithmeticFactor "%" ArithmeticTerm
20
     | ArithmeticFactor
21
  ArithmeticFactor ::=
22
23
       Integer
24
     | Identifier
      "-" ArithmeticExpr
25
     "(" ArithmeticExpr ")"
26
27
  BooleanExpr ::=
28
       BooleanTerm "or" BooleanExpr
29
30
     | BooleanTerm
  BooleanTerm ::=
31
       BooleanFactor "and" BooleanTerm
32
     BooleanFactor
33
34
  BooleanFactor ::=
35
       "true"
36
      "false"
     | "not" BooleanExpr
38
      ArithmetciExpr "eq" ArithmeticExpr
39
      ArithmetciExpr "neq" ArithmeticExpr
40
     | ArithmetciExpr "lt" ArithmeticExpr
41
     | ArithmetciExpr "gt" ArithmeticExpr
42
     | ArithmetciExpr "leg" ArithmeticExpr
43
      ArithmetciExpr "geq" ArithmeticExpr
44
     | "(" BooleanExpr ")"
```

Some of the non-terminals of this context-free grammar are reported directly in Haskell. That is, I defined an abstract syntax tree that also represents the intermediate representation of a program. This intermediate representation will be the result of the parser. Moreover, the presence of an intermediate representation permits us to apply optimizations at prior respect to the interpretation step. The following code snippet contains the definition of the abstact syntax tree.

```
data ArithmeticExpr
     = Add ArithmeticExpr ArithmeticExpr
2
     | Sub ArithmeticExpr ArithmeticExpr
3
     | Mul ArithmeticExpr ArithmeticExpr
4
     | Div ArithmeticExpr ArithmeticExpr
5
6
     | Mod ArithmeticExpr ArithmeticExpr
     | Neg ArithmeticExpr
      Constant Int
      Identifier String
9
10
     deriving (Eq, Show)
11
  data BooleanExpr
12
    = Boolean Bool
13
     | Not BooleanExpr
14
      Or BooleanExpr BooleanExpr
15
16
       And BooleanExpr BooleanExpr
17
      Equal ArithmeticExpr ArithmeticExpr
     | NotEqual ArithmeticExpr ArithmeticExpr
18
     | Less ArithmeticExpr ArithmeticExpr
19
20
     Greater ArithmeticExpr ArithmeticExpr
     LessEqual ArithmeticExpr ArithmeticExpr
21
     | GreaterEqual ArithmeticExpr ArithmeticExpr
22
     deriving (Eq, Show)
23
24
  data Command
25
     = Skip
26
27
     | Assignment String ArithmeticExpr
     | Branch BooleanExpr Block Block
28
29
     | Loop BooleanExpr Block
     deriving (Eq, Show)
30
31
  type Block = [Command]
```

#### The Parser

The parser can be viewed as a function from a string to a list of pairs of values and strings (Graham Hutton).

```
newtype Parser a = Parser {unwrap :: String -> [(a, String)]}
```

Note that the parser have a special function called unwrap that takes the function out from the parser. The parser is implemented in a "monadic" way. That is, I implemented the following interfaces: monad plus and monad alternative as suggested in Monadic Parsing in Haskell (Hutton & Meijer). In order to implement the monad interface I also implemented the functor and applicative interfaces as in the following code snippet.

```
instance Functor Parser where
fmap f p = Parser (\cs ->
    [(f a, cs') | (a, cs') <- unwrap p cs])

instance Applicative Parser where
pure a = Parser (\cs -> [(a, cs)])
p <*> q = Parser (\cs -> concat
    [unwrap (fmap a q) cs' | (a, cs') <- unwrap p cs])</pre>
```

The functor implementation for the parser implements the fmap function, that is the application of a function on a wrapped parser. Moreover, the applicative implementation for the parser implement both the function pure and the operator <\*>. The pure function takes a simple values and wraps it into a parser. The <\*> operator takes in input a function wrapped in a parser and another parser. The result is the application of the wrapped function onto the parser.

The next step is to implement the standard monad interface. Moreover, two more interfaces are implemented: MonadPlus and MonadAlternative. The plus operator defined on parsers concatenates the result of each one. Moreover, the MonadAlternative give us an operator <|> useful for combining parsers in a mutually exclusive way. The classes definition can be found in the following code snippet.

```
class (Monad m) => MonadPlus m where
zero :: m a
plus :: m a -> m a -> m a

class (MonadPlus m) => MonadAlternative m where
(<|>) :: m a -> m a -> m a
many :: m a -> m [a]
many m = some m <|> return []
some :: m a -> m [a]
some m = liftA2 (:) m (many m)
```

Note that the function liftA2 is the composition of fmap and the applicative operator <\*>. The functions many and some are called *combinators* and are used to define the concept of repeated parsing. The many function refers to zero to any number of applications of a parser while the some function refers to at least one to any number of applications of a parser. The implementation for the parser of the monad sequencing and the other functions and operators described before is the following.

```
instance Monad Parser where
2
  return a = pure a
  p >>= f = Parser (\cs -> concat
     [unwrap (f a) cs' | (a, cs') <- unwrap p cs])
4
5
  instance MonadPlus Parser where
6
7
  zero = Parser (const [])
8
  p `plus` q = Parser (\cs -> unwrap p cs ++ unwrap q cs)
9
  instance MonadAlternative Parser where
10
  (<|>) p q = Parser (\cs ->
11
     case unwrap (p `plus` q) cs of
12
       [] -> []
13
       (x : _) \rightarrow [x])
14
```

The zero operator defines what is an empty parser. Note that in this context an empty parser is a *failed* parser, that is a parser that results from a syntactical error. The plus operator concatenates the results of two individual parsers. Using the monadic definition of parser, it permits us to easily build a parser for each structure of the programming language, without having to handle the eventual parsing errors individually. For example, it's possible to define a parser for symbols, identifiers and integers as in the following code snippet. Moreover, since the parser implements the MonadAlternative interface described above, the combination of multiple parsers is straightforward and easily parallelizable.

```
item :: Parser Char
  item = Parser (\case "" -> []; (c : cs) -> [(c, cs)])
  satisfy :: (Char -> Bool) -> Parser Char
4
  satisfy p = do c <- item; if p c then return c else zero
  token :: Parser a -> Parser a
  token p = do space; v <- p; space; return v
  space :: Parser String
10
  space = many $ satisfy isSpace
11
12
13 identifier :: Parser String
  identifier = token $ some $ satisfy isLetter
14
15
16
  constant :: Parser Int
17
  constant = read <$> token (some $ satisfy isDigit)
18
  char :: Char -> Parser Char
19
20 char c = satisfy (c ==)
```

That is, I firstly defined a item function that reads a character from the string. Then I defined a function called satisfy that apply a constraint to the character read by the parser. This function returns an zero parser if the constraint is not satisfied. In the end, using both the combinators many and some, I built parsers for identifiers, constants and also spaces that are the main blocks of the context-free grammar already defined. In the same way, it's possible to define a parser for other constructs, such as keywords and symbols.

```
keyword :: String -> Parser String
keyword cs = token $ word cs

word :: String -> Parser String
word [c] = do char c; return [c]
word (c : cs) = do char c; word cs; return (c : cs)

symbol :: Char -> Parser Char
symbol c = token $ char c
```

In order to build parsers for both arithmetic and boolean expression the <|> operator between parsers is used. So, I define the parser for arithmetic expressions using other sub-parsers that are used in order to maintain the operators precedence.

```
arithmeticExpr :: Parser ArithmeticExpr
2
  arithmeticExpr = do
    a <- arithmeticTerm
3
4
      do symbol '+'; Add a <$> arithmeticExpr
       <|> do symbol '-'; Sub a <$> arithmeticExpr
5
       <|> do return a
6
  arithmeticTerm :: Parser ArithmeticExpr
  arithmeticTerm = do
9
10
    a <- arithmeticFactor
      do symbol '*'; Mul a <$> arithmeticTerm
11
12
      <|> do symbol '/'; Div a <$> arithmeticTerm
       <|> do symbol '%'; Mod a <$> arithmeticTerm
13
       <|> do return a
14
```

```
arithmeticFactor :: Parser ArithmeticExpr
arithmeticFactor =

do Constant <$> constant

<|> do Identifier <$> identifier

<|> do symbol '-'; Neg <$> arithmeticExpr

<|> do symbol '('; a <- arithmeticExpr; symbol ')'; return a
```

The parser for boolean expressions is similar to the parser for arithmetic expressions and so it's omitted in this documentation. In the end we have a parser for every command described in the grammar. So, I defined a parser for the following commands: skip, assignment, if-then-else, and while-do.

```
assignment :: Parser Command
  assignment = do
     d <- identifier
3
     symbol '='
4
5
     a <- arithmeticExpr
     symbol ';'
6
     return (Assignment d a)
  branch :: Parser Command
9
  branch = do
10
     keyword "if"
11
12
     symbol '('
     b <- booleanExpr
13
     symbol ')'
14
     keyword "then"
15
     c1 <- block
16
17
       keyword "else"
18
       c2 <- block
19
       keyword "end if"
20
       symbol ';'
21
22
       return (Branch b c1 c2)
23
       <|> do
         keyword "end if"
24
         symbol ';'
25
         return (Branch b c1 [Skip])
26
27
28
  loop :: Parser Command
  loop = do
29
     keyword "while"
30
     symbol '('
31
     b <- booleanExpr
32
     symbol ')'
33
     keyword "do"
34
     c <- block
35
     keyword "end while"
36
     symbol ';'
37
38
     return (Loop b c)
39
  skip :: Parser Command
40
  skip = do
41
     keyword "skip"
42
     symbol ';'
43
44
     return Skip
```

It's important to notice that the grammar also allows for if-then statements (i.e. without the else command block). A parser that works on both if-then-else and if-then statements is implemented by combining the two individual parsers using the <|> operator. Moreover, using the many combinator and the <|> operator, the parsers for both multiple commands and a single command are straightforward.

```
block :: Parser Block
block = many command

command :: Parser Command
command = assignment <|> branch <|> loop <|> skip
```

The parser for the entire program is defined as in the following code snippet.

```
program :: Parser Block
program = do keyword "shrimp"; block

parse :: String -> Result (Block, String)
parse cs = case unwrap program cs of
[] -> Error EmptyProgram
[(b, cs)] -> Ok (b, cs)
```

# The Optimizer

The *optimization* process is an intermediate step between the parsing and the interpretation of the program itself. Currently, the main optimization step is related to the execution of constant values. That is, if an expression in a loop is defined only on constant values, it's better to optimize the computation of that expression by replacing it with the result. This procedure is done before the interpretation of the program. For example, consider the following arithmetic expression, expressed in intermediate representation, that we wish to optimize.

If we apply the optimization step to this arithmetic expression, we obtain the equivalent but more efficient arithmetic expression.

```
let expr' = Div (Mul (Identifier "x") (Constant 2)) (Constant 10)
```

The implementation of the *optimization* process in Haskell is straightforward, due to simple recursion functions. A very similar optimization process is also implemented on boolean expressions. The *optimization* process also includes a basic optimization on commands such as skip, if-then-else and while-do. First of all, all the skip commands are removed from the intermediate representation. Moreover, if the condition of a if-then-else command is always *true* then the entire statement is replaced with the first block of commands. In a similar way, if the condition is always *false* then the entire statement is replaced with the second block of commands. Furthermore, this approach is also used for while-do commands. That is, if the condition of a while-do command is always *false* then the entire statement is completely removed. However, if the condition is always *true* then an exception named *Infinite Loop* is raised. In other words, the optimizer is capable of detecting trivial infinite loops and prevents the interpretation of such programs.

## The Interpreter

Finally, the obtained intermediate representation is interpreted by the interpreter. The interpreter scan the intermediate representation using *depth-first traversal* on the n-ary tree that compose the intermediate representation itself. Before introducing the execution of the interpreter on an intermediate representation, some useful data types are defined in order to handle errors.

```
data Exception
2
     = EmptyProgram
       InfiniteLoop
3
     | DivisionByZero
4
     | UndeclaredVariable String
5
     deriving (Show)
7
  data Result a = Ok a | Error Exception
8
9
  instance Functor Result where
10
11
     fmap f (Ok v) = Ok (f v)
     fmap _ (Error e) = Error e
12
13
  instance Applicative Result where
14
15
     pure v = 0k v
     (<*>) (0k f) (0k v) = 0k (f v)
17
     (<*>) (Error e) _ = Error e
     (<*>) _ (Error e) = Error e
18
19
  instance Monad Result where
20
21
     (>>=) (0k v) f = f v
     (>>=) (Error e) _ = Error e
22
23
  exception :: Exception -> a
24
  exception e = errorWithoutStackTrace $ show e
```

As one can see, the Result data type is a polymorphic type that can be either a Ok or a Error. The Error type also encapsulate an exception, one of the listed above. Moreover functor, applicative and monad interfaces are implemented in order to apply the needed operators directly on results. The main function that executes a block (i.e. a list of command) is reported in the following code snippet.

```
execute :: State -> Block -> State
  execute s [] = s
3
  execute s (Skip : cs) = execute s cs
  execute s ((Assignment d a) : cs) =
4
    case evalArithmetic s a of
5
      Ok v -> execute s' cs
7
         where
           s' = insert d v s
8
      Error e -> exception e
9
  execute s ((Branch b cs' cs'') : cs) =
10
    case evalBoolean s b of
11
       Ok True -> execute s (cs' ++ cs)
12
      Ok False -> execute s (cs'' ++ cs)
13
14
      Error e -> exception e
  execute s (c@(Loop b cs') : cs) =
15
    execute s (Branch b (cs' ++ [c]) [Skip] : cs)
```

The implementation of the execution of a while-do resembles how it's evaluated in operational semantics, i.e. by "wrapping" it in a if-then-else command statement.

The implementation of the evaluation of arithmetic expressions make *heavily* use of the methods exposed by the applicative interface. Moreover, the liftA2 function is used in order to make the functions more compact.

```
evalArithmetic :: State -> ArithmeticExpr -> Result Int
  evalArithmetic _ (Constant v) = Ok v
  evalArithmetic s (Identifier d) =
     case search d s of
5
       Just v -> Ok v
       Nothing -> Error (UndeclaredVariable d)
6
  evalArithmetic s (Add a1 a2) = liftA2 (+) v1 v2
7
8
9
       v1 = evalArithmetic s a1
10
       v2 = evalArithmetic s a2
11
  evalArithmetic s (Sub a1 a2) = liftA2 (-) v1 v2
12
       v1 = evalArithmetic s a1
13
       v2 = evalArithmetic s a2
14
  evalArithmetic s (Mul a1 a2) = liftA2 (*) v1 v2
15
     where
16
       v1 = evalArithmetic s a1
17
       v2 = evalArithmetic s a2
18
  evalArithmetic s (Div a1 a2) = seqM2 safeDiv v1 v2
19
20
     where
       v1 = evalArithmetic s a1
21
       v2 = evalArithmetic s a2
22
  evalArithmetic s (Mod a1 a2) = seqM2 safeMod v1 v2
23
    where
24
       v1 = evalArithmetic s a1
25
26
       v2 = evalArithmetic s a2
  evalArithmetic s (Neg a) = negate <$> v
27
    where
28
       v = evalArithmetic s a
29
```

In this implementation, I also used the functions safeDiv, safeMod and seqM2 which implementation is showed in the following code snippet. In other words, the seqM2 is a custom function that implements binary sequencing, similarly to the »= operator.

```
1 safeDiv :: Int -> Int -> Result Int
  safeDiv _ 0 = Error DivisionByZero
  safeDiv u v = Ok (div u v)
3
  safeMod :: Int -> Int -> Result Int
5
  safeMod _ 0 = Error DivisionByZero
6
7
  safeMod u v = Ok (mod u v)
  seqM2 :: (Monad m) => (a -> b -> m c) -> m a -> m b -> m c
9
  seqM2 f x y = join $ liftA2 f x y
10
11
  join :: (Monad m) => m (m a) -> m a
  join m = m >>= id
```

The implementation of the evaluation of boolean expressions is very similar to the one for arithmetic expressions, so it's omitted.

## Conclusion

The monadic implementation of the parser give us a very simple way of concatenate and combine multiple parsers of sub-grammars. Also, it's very easy to extend the grammar of the language in order to include other commands or statements. Moreover, the use of an intermediate representation permits us to apply post-processing or optimizations and make the interpretation itself straightforward.

Future works may include the introduction of other types for variables, such as boolean types. Another extension of this work consists of adding useful information about the parsing errors, i.e. missing tokens and relevant row and column locations in the source code where the error occurred. However, other improvements can be done in the optimization step. That is, one can implement more "aggressive" optimizations of the intermediate representation based on the expected state of memory of the program during its execution.
